Induced vortex tunneling in a superconducting wire

S. Khlebnikov
Department of Physics, Purdue University, West Lafayette, IN 47907, USA

We consider induced topological transitions in a wire made from cylindrical superconducting film. During a transition, a pulse of electric current causes transport of a virtual vortex-antivortex pair around the cylinder. We consider both the instanton approach, in which the transition is viewed as motion of vortices in the Euclidean time, and the real-time dual formulation, in which vortices are described by a fundamental quantum field. The instanton approach is convenient to discuss effects of the environment, while in the dual formulation we show that there exists a potentially useful adiabatic regime, in which the probability to create a real vortex pair is exponentially suppressed, but the total transport of the vortex number can be of order one.

I. INTRODUCTION

Tunneling of magnetic flux across weak superconducting links of various nature is of interest for both fundamental physics and applications. In particular, devices using Josephson junctions have been discussed recently in connection with proposals for quantum computing (qubits). (For a review of various types of superconducting qubits, see ref. [1].) Such devices (SQUIDs) can be, for many purposes, reduced to just a few degrees of freedom, so it becomes possible to numerically simulate their quantum behavior. In this way, one can discuss not only the amplitude transfer between the basis states, but also the residual excitation due to population of the higher levels [2,3].

As the strength of the weak link is increased, by going from a Josephson contact to a narrow wire, and then to a wider wire, superconductivity becomes more robust, and the tunneling rate drops. In ultrathin wires, with widths $L_x \ll \xi$, where ξ is the Ginzburg-Landau coherence length, the relevant tunneling events are quantum phase slips [4,5]. Crossover to the wide-wire case occurs at widths $L_x \sim \xi$, and for wider wires transport of flux happens via formation of vortices.

Robustness of superconductivity in wires with $L_x \gg \xi$ can be useful in applications that require long coherence time, such as qubits. Indeed, we expect that in a suitable implementation such a wire will not be subject to any shunting effects except for thermal quasiparticles. Possible implementations include a wire defined lithographically on a substrate or a multiwall carbon nanotube coated with a superconducting film. In either case, the superconducting circuit has to be closed to allow a persistent current, which presumably can be done using ordinary bulk superconductors.

On the other hand, when a wire with $L_x \gg \xi$ is used in place of a weak link, inducing a transition between the basis states of the qubit becomes a nontrivial matter, since flux does not travel easily across wider wires. We propose to use for this purpose a pulse of electric current along the wire, which can be produced by coupling the qubit, either directly or inductively, to some external circuit. The pulse will lower the potential barrier separating the basis states and thus encourage the motion of flux across the wire. We call this process *induced* vortex tunneling.*

Because this process involves many degrees of freedom, the theory of it has to be constructed from an entirely different standpoint than the few-degree-of-freedom modeling common in the theory of SQUIDs. In this paper we develop and compare two approaches. One approach uses instantons, i.e., Euclidean solutions, which in our case correspond to motion of vortices and antivortices across the wire in Euclidean (imaginary) time. This approach makes it possible to discuss the effects of the environment (specifically, fermions at the vortex cores) on tunneling, but for calculations of the residual excitation left in the system by the pulse, is less convenient than the other approach, based on duality. In the dual formulation, vortices are described by a fundamental quantum field, and the tunneling rate appears as a finite-size effect due to mode quantization in a confined geometry.

For definiteness, we consider cylindrical geometry, in which the wire is formed by a thin superconducting film on an insulating cylindrical surface. The "width" L_x of the wire is the circumference of the cylinder. Although this may not be the simplest geometry to manufacture, it has the advantage of simple (periodic) boundary conditions in the x direction. Results for other geometries, e.g., thin strips should be substantially similar.

Short Abrikosov flux lines that can propagate in the film will be referred to as vortices and antivortices, de-

*As we explain in more detail below, the pulse of current is supposed to enhance tunneling of flux but *not* induce real-time, over-barrier transitions. Thus, our problem is quite distinct from that of a resistive state in thin wires [6] or films [7]. In particular, real-time classical simulations based on the time-dependent Ginzburg-Landau equation are clearly inapplicable in our case.

pending on which direction the flux points. Motion of the flux across a cylindrical wire can be viewed as creating a vortex-antivortex pair on one side of the cylinder, transporting them along the circumference, and annihilating them on the other side, see Fig. 1. This process has been discussed in various contexts in the literature [8–10]. Here, we present a detailed calculation of the rate, including the effect of core fermions, and a discussion of the residual excitation.

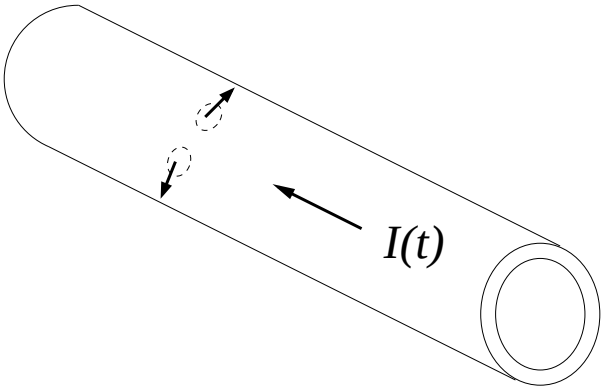

FIG. 1. A segment of wire made from cylindrical superconducting film. A pulse of current $I(t)$ induces transport of a virtual vortex-antivortex pair around the cylinder.

Vortex instantons have been used to discuss the phenomenon of quantum creep [11]. That discussion employed the ordinary non-relativistic vortex action. In our case, since a tunneling event requires formation of a vortex-antivortex pair, we are constrained to use a "relativistic" action, with the speed of light replaced by some other limiting speed c_1. We will see that in this "relativistic" case, instantons are characterized by large (Euclidean) velocities and correspondingly short timescales, one of the consequences being that the core contribution to the vortex mass is greatly reduced.

We stress that when we speak about production of a vortex pair, transporting vortices around the cylinder, etc. we mean a *virtual* process, i.e., tunneling. Production of real vortices is detrimental to our goal, since these vortices would be easily "detected" by the environment (e.g., by electrons at the vortex cores), and that would result in rapid decoherence of quantum superpositions that we intend to form. To prevent decoherence, induced transitions should leave as little imprint on the environment as possible. The main result of the present work is that it is possible, at least theoretically, to use a slowly (adiabatically) changing current that has an exponentially small probability to create a real vortex but still leads to a sizeable transport of the vortex number around the cylinder.

At the first-quantized level, the dual description we use coincides with that employed in the theory of vortex transport in arrays of Josephson junctions [12]. However, to consider effects of zero-point vortex-antivortex pairs fluctuating "in and out of existence", we need to apply duality at the second-quantized level. In a second-quantized description, vortices are represented by a fundamental quantum field. Such a description was used in refs. [13,14] to study nucleation of vortex-antivortex pairs in the presence of a static supercurrent. The main differences between that problem and ours are that in our case the process is, first, time-dependent and, second, avoids as much as possible production of real vortex pairs.

The paper is organized as follows. Sect. II describes the duality map. Effects of core fermions and of the vortex-antivortex potential on vortex tunneling are discussed, using the instanton picture, in Sect. III. This discussion gives us confidence that the linear equation (9) obtained in Sect. 2 indeed captures the essential physics of the process. Sect. IV contains definitions of the average vortex current, which is used to measure the tunneling amplitude, and of the residual excitation left in the system after the pulse (the number of real vortices produced). In Sect. V we consider the adiabatic limit (a slowly changing current) and show that it is possible to have a sizeable amplitude transfer with exponentially small residual excitation. Some numerical estimates are given in Sect. VI. We find that for a film of thickness $d = 10$ nm, a suitable width of the wire is of order 1 μm. Sect. VII is a conclusion.

II. DUALITY MAP

The original quantum description of a superconductor contains the usual vector potential A_μ as well as fields corresponding to other degrees of freedom: fluctuations of the order parameter, normal electrons at vortex cores, etc. We introduce field a_λ, dual to the electromagnetic field A_μ, by rewriting the corresponding factor in the functional integral as a Gaussian integral:

$$\exp\left(-\frac{id}{16\pi\hbar}\int F_{\mu\nu}^2 d^2x dt\right) = \text{const.}\times$$
$$\int \mathcal{D}a_\mu \exp\frac{i}{\hbar}\int\left(\frac{gc}{4\pi}\epsilon^{\mu\nu\lambda}F_{\mu\nu}a_\lambda + \frac{g^2c^2}{2\pi d}a_\lambda^2\right)d^2x dt\,. \quad (1)$$

Here d is the film's thickness,

$$g = \frac{2e}{\hbar c}\,, \quad (2)$$

e is the magnitude of electron charge ($e > 0$), and c is the speed of light. We have already incorporated the condition that the film is thin, so that parallel fields penetrate inside undiminished. Greek indices run over values 0,1,2; Latin indices over 1,2. Sums over repeated indices are implied.

The next step is to separate the original field A into $A^{(\text{vort})}$, which consists of narrow flux tubes attached to vortices, and the remaining long-range part $A^{(\text{long})}$. In thin films, the screening length for perpendicular magnetic fields is very large [15], so a narrow flux tube does

not account completely for the magnetic field of a vortex: part of the field will appear in $A^{(\mathrm{long})}$ and will be responsible for long-range interactions between the vortices. However, the electric field of a moving vortex is confined to the vortex core [16,17,10], and that makes introduction of the flux tubes useful. For the field strength we have

$$F_{\mu\nu} = F^{(\mathrm{long})}_{\mu\nu} + F^{(\mathrm{vort})}_{\mu\nu} \ . \tag{3}$$

We define a (conserved) current of vortices as

$$J^\lambda \equiv -\frac{gc}{4\pi}\epsilon^{\mu\nu\lambda}F^{(\mathrm{vort})}_{\mu\nu} \ . \tag{4}$$

Thus a state with $J_0 = c\delta(\mathbf{x})$ carries precisely a unit flux quantum $\Phi_0 = 2\pi/g$ of $F^{(\mathrm{vort})}$.

To obtain a dual description of vortices, we introduce a new complex field χ with a unit charge with respect to the field a. The action of the vortex field is taken in the form

$$S_\chi = \int d^2x dt \left[|\partial_t\chi + (ic/\hbar)a_0\chi|^2 - c_1^2\,|\partial_i\chi + (i/\hbar)a_i\chi|^2 - M^2(t)|\chi|^2 \right] \ , \tag{5}$$

where $M(t)$ is half of the pair-production frequency. During a pulse of current, this frequency is time-dependent. Eq. (5) is a "relativistic" action, except that the role of the speed of light is played by some other speed c_1, cf. refs. [13,14]. We will discuss the value of c_1 in Sect. VI.

The "relativistic" form of (5) may seem ad hoc, but in fact the form of the vortex action is highly constrained by symmetries. For example, the presence of a conserved vortex current dictates that χ should be a complex field, while the possibility of pair production dictates that the kinetic term should be quadratic in the time derivative. The absence of terms with higher spatial derivatives is a good approximation as long as wavenumbers do not exceed a certain ultraviolet cutoff, which we expect to be of order of the lattice spacing. Finally, self-interaction of the vortex field (higher-order terms in χ) can be neglected as long as vortices are sufficiently rare.

The simple action (5) neglects other degrees of freedom, in particular, fermions at the vortex core [18]. These are nearly gapless and, as well known, cause large friction for slow vortex motions [19]. For a tunneling process, involving virtual vortices only, the expected effect of such a dissipative environment is a reduction in the tunneling rate [20]. We analyze this effect in the next section and find that for rapid, large-frequency Euclidean motions corresponding to tunneling, the role of dissipative processes is greatly reduced, so much so that they do not affect the main exponential factor in the tunneling rate, but can only affect the preexponent. Because our main conclusions are based on the value of the exponential factor, we take

$$S_{\mathrm{dual}} = \int d^2x dt \left(\frac{gc}{4\pi}\epsilon^{\mu\nu\lambda}F^{(\mathrm{long})}_{\mu\nu}a_\lambda + \frac{g^2c^2}{2\pi d}a_\lambda^2 \right) + S_\chi \tag{6}$$

as the full action of our dual description.

The vortex current in this description is given by the usual formula $J^\lambda = -\delta S_\chi/\delta a_\lambda$. In particular, the spatial components are

$$J^i = -\frac{i}{\hbar}c_1^2\left(\chi^\dagger\partial_i\chi - \partial_i\chi^\dagger\chi + \frac{2i}{\hbar}\chi^\dagger\chi a_i\right) \ . \tag{7}$$

From (6), we obtain an equation for a in the form

$$\frac{g^2c^2}{\pi d}a^\lambda = -\frac{gc}{4\pi}\epsilon^{\mu\nu\lambda}F^{(\mathrm{long})}_{\mu\nu} + J^\lambda \ . \tag{8}$$

Combined with eqs. (3) and (4) this is seen to be completely equivalent to the saddle-point condition for the integral (1), i.e., to the original definition of a.

Equation of motion for χ is obtained from (5) and reads

$$[\partial_t + (ic/\hbar)a_0]^2\chi - c_1^2[\partial_i + (i/\hbar)a_i]^2\chi + M^2\chi = 0 \ . \tag{9}$$

When we use (8) in this equation, we obtain an interaction of vortices with the long-range field $F^{(\mathrm{long})}_{\mu\nu}$. (The interaction with the short-ranged J^λ is negligible if vortices are rare.) As we have mentioned above, the field $F^{(\mathrm{long})}_{\mu\nu}$ includes the long-range tails [15] of vortex magnetic fields and thus gives rise to a logarithmic interaction between vortices. Accordingly, the frequency M in (9) should be understood as being due to the vortex core only. However, for instanton processes, involving a single vortex-antivortex pair, we can, instead of keeping track of the vortex contribution to a^λ, model the vortex-antivortex potential by making M position-dependent. Moreover, as we will see in the next section, for calculation of the tunneling exponent, such x-dependent frequency can be replaced simply by its average value along the vortex path. Within this model, and with the short-ranged J^λ dropped from (8), components of a do not contain any fields due to vortices and reduce to external $\mathbf{E}$ and $\mathbf{B}$ fields only:

$$(a_0, a_1, a_2) = \frac{d}{2gc}(B_z, -E_y, E_x) \ . \tag{10}$$

Eq. (9) is a second-quantized description of vortices, which allows us to study effects due to virtual vortex-antivortex pairs. Similar descriptions were used previously in refs. [13,14] to study the instability of a static supercurrent via production of real vortex-antivortex pairs. In the limit when vortex-antivortex fluctuations are neglected (*not* a suitable limit here), eq. (9) gives rise to a first-quantized description, in which a vortex of mass $m = \hbar M/c_1^2$ moves under action of a Lorentz force built from dual electric and magnetic field. These fields, $\mathbf{e} = -\nabla a_0 - (1/c)\partial_t\mathbf{a}$ and $\mathbf{b} = \nabla\times\mathbf{a}$ can be expressed through the electric current and charge density, using (10) and Maxwell's equations. The resulting expressions coincide with those appearing in the first-quantized theory of ref. [12].

For a static supercurrent I in the y direction, we would have $a_1(t) \propto It$. In contrast, the adiabatic case considered below corresponds to a slowly changing pulsed a_1: $a_1(t \to \pm\infty) = 0$.

An additional constant "magnetic" field $\mathbf{b}$ can be used to describe a Magnus force on the vortex. However, as we will find in the next section, for tunneling processes the Magnus force is canceled, to a very high accuracy, by the spectral flow force [21–23] due to core fermions. Accordingly, we set the total effective Magnus force to zero: $\mathbf{b} = 0$.

Eq. (9) simplifies further if we restrict our attention to the cylindrical geometry of Fig. 1. A pulse of electric current will be applied lengthwise, in the y direction. The resulting field E_y will induce a virtual pair of vortex and antivortex to travel along the circumference of the cylinder (i.e., in the x direction). So, we set $E_x = B_z = 0$, and $E_y = E(t)$. For the present configuration, E is independent of x and y. Thus, the equation of motion takes the form

$$\ddot{\chi} - c_1^2\partial_y^2\chi - c_1^2\left[\partial_x - i\frac{d}{4e}E(t)\right]^2\chi + M^2(t)\chi = 0\ . \quad (11)$$

Although we will not need any such relation in what follows, we note that the two time-dependent parameters in (11), E and M, can be expressed through a single function of time—the electric current (see ref. [24] for details).

III. INSTANTONS AND THE EFFECTS OF THE ENVIRONMENT

It is well known that motion of vortices in superconductors is subject to strong renormalization effects due to the "environment" of normal electrons at the vortex cores. For low-frequency motions, in very clean superconductors, the main effect is a drastic reduction of the limiting speed c_1 in eq. (9). Indeed, in such cases it is natural to expect that c_1 will be equal to the critical velocity of the superconductor $v_{\rm cr} = \Delta/v_F$, where Δ is the value of the gap outside the core. At larger speeds, the vortex becomes a "tachyon" and causes an instability via production of quasiparticles from the core. Equivalently, the small $c_1 = v_{\rm cr}$ can be interpreted as a large value of the inertial mass m of the vortex, since from (9)[†]

$$m = M/c_1^2\ . \quad (12)$$

This estimate is consistent with direct calculations [25] of the inertial mass (provided the frequency M is understood as the core contribution only).

[†]In this section, we set $\hbar = 1$.

Situation, however, is entirely different at large frequencies, or short timescales, which as we will see below is the case relevant to tunneling. The characteristic frequency associated with the fermionic response is determined by the "minigap" $\omega_0 \sim \Delta^2/\epsilon_F$, separating different states at the vortex core [18]. When the timescale of the vortex motion is much shorter than ω_0^{-1}, the response and the contribution of fermions to the inertial mass will be diminished. Here, we calculate this effect for the vortex motion corresponding to our tunneling problem. The motion takes place in the Euclidean (imaginary) time. We will employ the kinetic equation [23] for core states, which gives their evolution in real time, and then analytically continue the results to the Euclidean domain.

The low-lying ("anomalous") branch of fermion spectrum [18] at the vortex core runs in energy approximately from $-\Delta$ to Δ (for a review and further references, see ref. [26]). This branch is characterized by two quantum numbers: k_z, the momentum in the z direction (which in our case is perpendicular to the film), and the angular momentum l. For a vortex at rest, the energy levels are given approximately by $E_l(k_z) = -\omega_0(k_z)l$, with $\omega_0(k_z) = \Delta^2/2v_Fk_\perp$, and $k_\perp^2 = k_F^2 - k_z^2$. In particular, $\omega_0(0) = \Delta^2/2v_Fk_F$ [23]. Motion of the vortex relative to the superfluid results in an interaction Hamiltonian and can cause transitions between different core levels. The distribution function n in general depends on the quantum numbers k_z and l and their conjugate coordinates z and ϕ. If n is independent of z, the kinetic equation [23] reads

$$\frac{\partial n}{\partial t} - \omega_0(k_z)\frac{\partial n}{\partial \phi} + \mathbf{k}\times\mathbf{v}(t)\frac{\partial n}{\partial l} = 0\ , \quad (13)$$

where $\mathbf{k} = (k_\perp\cos\phi, k_\perp\sin\phi, k_z)$, and $\mathbf{v}$ is the vortex velocity. Note that we write the kinetic equation in the collisionless (Vlasov) approximation. This is appropriate whenever the characteristic timescale of the motion is much shorter than the collision time.

Solutions to eq. (13) can be obtained analytically for any form of the vortex velocity. Here we consider the case of main relevance to us, when the velocity is in the x direction at all times. Then, the zero-temperature solution is a step-function

$$n(\phi, l; t) = \theta\left[l + k_\perp\omega_0\int dt' G_R(t-t')h(\phi; t')\right]\ , \quad (14)$$

where

$$h(\phi; t) = v(t)\cos\phi + \omega_0^{-1}\partial_t v(t)\sin\phi\ , \quad (15)$$

and G_R is the retarded Green function for $\partial_t^2 + \omega_0^2$: $G_R(t<t') = 0$, $G_R(t>t') = \omega_0^{-1}\sin[\omega_0(t-t')]$. (More generally, the step-function can be replaced by an arbitrary function in (14), so finite-temperature solutions can also be constructed.) Eq. (14) describes excitation of the core system, originally in its ground state, by the vortex motion.

If velocity $v(t)$ is peaked around $t = 0$ at the timescale t_1 shorter than both ω_0^{-1} and the "observation time" t, we can replace it in (15) with a pulse of the form $v(t) = x\delta(t)$, where x is the displacement. This yields $n(\phi, l; t) = \theta(l)$ for $t < 0$, and

$$n(\phi, l; t) = \theta\left[l + k_\perp x \sin(\omega_0 t + \phi)\right] \tag{16}$$

for $t > 0$. Integrating over all modes, we obtain the total momentum transferred to electrons upon a vortex displacement x:

$$p_x(x) = \frac{d}{2} x \int_{-k_F}^{k_F} \frac{dk_z}{2\pi} k_\perp^2 \sin\omega_0 t \ , \tag{17}$$

while for p_y the sine gets replaced by $\cos\omega_0 t$. The remaining dependence on t means that even after the displacement has been completed, and the vortex has stopped, fermions at the core continue to oscillate ("wobble").

Tunneling in a wire can be visualized as motion in Euclidean time of a vortex and an antivortex, each by half-width of the wire, or alternatively as motion of the vortex alone by the full width L_x. For definiteness, we will discuss the latter process. We refer to it as an instanton. The instanton has two timescales associated with it: time τ_0 it takes to create or destroy a vortex-antivortex pair, and time τ_1 it takes the vortex to travel the distance L_x. Both τ_0 and τ_1 are variational parameters that adjust themselves to achieve the largest tunneling amplitude.

A natural estimate for τ_0 is $\tau_0 \sim M^{-1}$, and we will see that this estimate is unaffected by the presence of the environment. We will also find that in the limit when instantons are dilute, i.e., when the vortex motion has a large Euclidean action, we have $\tau_1 \gg M^{-1}$, but still $\omega_0\tau_1 \ll 1$. So, to understand the effect of the environment on τ_1, we analytically continue to $t = -i\tau$ and expand in small $\omega_0\tau$. The change in the vortex momentum is opposite to (17), and the corresponding contribution to the Euclidean action of the vortex is

$$i\int_0^{L_x} p_x dx = \frac{d}{16} L_x^2 k_F^3 \omega_0(0)\tau \ . \tag{18}$$

In our case, we need to replace τ with τ_1, and although this just invalidates the approximation under which (17) was obtained, and the precise form of the velocity pulse begins to matter, we can still obtain an order-of-magnitude estimate for $\int p_x dx$. Let us first obtain this estimate for the case when the instanton gas just ceases being dilute, and τ_1 becomes of order M^{-1}. In the case of induced tunneling, parameters M and Δ should be taken at time when the transition actually occurs. However, because (18) is now proportional to Δ^2/M, and M scales as Δ^2, we can as well use the unperturbed, equilibrium values. Using $M \sim (k_F d)\epsilon_F$, and $\omega_0(0) = \Delta^2/4\epsilon_F$, we estimate (18) as $(k_F L_x)^2(\Delta/\epsilon_F)^2/64$. This is small for typical values $k_F L_x \sim 10^3$ and $\Delta/\epsilon_F \sim 10^{-3}$, but can become large for larger L_x. In the latter case, or in the dilute regime when τ_1 is sufficiently large in comparison with M^{-1}, the action (18) begins to play a role in determining the value of the variational parameter τ_1.

To see how that happens, consider the Euclidean action for a single vortex, without the environment correction:

$$S_E = \int d\tau M(1 + v_E^2)^{1/2} \ , \tag{19}$$

where v_E is the Euclidean velocity, and we use units with $c_1 = 1$. Strictly speaking, the mass M should be made x-dependent, to include the vortex-antivortex potential. For now, however, we will consider it as some constant average mass; we will justify this replacement later. Then, during the vortex motion, v_E is constant, and $\tau_1 = L_x/v_E$. The exponential factor in the tunneling amplitude in this case is given by

$$\int \frac{d\tau_1}{\tau_1} e^{-S_E} = \int dv_E \exp\left[-\frac{ML_x}{v_E}(1 + v_E^2)^{1/2} - \ln v_E\right] \ . \tag{20}$$

For large values of the product ML_x, the saddle-point value of v_E is large: $v_E = (ML_x)^{1/2}$, while $\tau_1 = (L_x/M)^{1/2}$. The saddle-point value of the exponent in this case is

$$S_E = ML_x/c_1 + O(1) \tag{21}$$

(we have restored c_1 in this formula), so the limit of large ML_x is precisely the limit when the instanton gas is dilute. Now, including the correction (18), with $\tau \sim \tau_1$, we obtain a new effective action, which in the limit of large v_E has the form

$$S_{\text{eff}} \approx ML_x + \frac{ML_x}{2v_E^2} + CL_x^3 k_F^3 \omega_0(0)\frac{d}{16 v_E} + \ln v_E \ , \tag{22}$$

where C is a numerical coefficient of order 1. Depending on the parameters, either the second or the third term in (22) can be more important in determining the saddle point value of v_E. In either case, however, the effective action on the saddle point will have the same form as eq. (21). We conclude that the longitudinal momentum transfer from the vortex to fermions at the core affects at most the tunneling preexponent, but not the main exponential factor.

The $\exp(-\text{const}.L_x)$ form of the tunneling exponent had been discussed in the literature for various systems supporting vortices [8,9]. The main point of this section is that it holds also for the "relativistic" action (19), and in this case the value of the exponent is not affected by the longitudinal correction (18).

Turning to the transverse momentum, and following the steps that led to eq. (18), we obtain the following contribution to the Euclidean action:

$$ip_y(L_x)y = i\frac{k_F^3 d}{3\pi} L_x y\left[1 + O(\omega_0^2\tau_1^2)\right] \ , \tag{23}$$

where y is a small displacement in the y direction. Unlike (18), this contribution is purely imaginary: it gives rise to phase differences between vortex paths lying at different values of the lengthwise coordinate y. If significant phase differences existed, the tunneling amplitude would be drastically reduced. However, the magnitude of the leading term in (23) is such that, for k_F equal to the value of the Fermi momentum outside the vortex core, it precisely cancels the action corresponding to the Magnus force. This is the well known cancellation of the Magnus force by the force due to spectral flow [21–23,27,28]. The remaining correction in (23) is of order ω_0^2 and is already quite small. Still, an even more complete cancellation can be achieved, because k_F, which measures the electron density at the core, is also a variational parameter and does not have to coincide with the value outside the core. As eq. (23) shows, a tiny self-adjustment of k_F is sufficient to render the effective Magnus force exactly zero.

Finally, we need to restore the effect of the vortex-antivortex potential. As before, we consider the situation when, upon creation of a virtual vortex-antivortex pair, the antivortex stays in place, while the vortex makes a complete circle around the cylinder. Then, for the vortex action, we can still use eq. (19) but M should now be replaced by some (periodic) function of x. Accordingly, v_E is no longer a constant. We notice, however, that the reason why (19) previously simplified into (21) was not that v_E was constant, but that it was large: $v_E \gg 1$. This still applies now, during most of the path. Taking this limit in eq. (19) with $M \to M(x)$, we obtain

$$S_E \approx \frac{1}{c_1} \int M(x) dx \ , \tag{24}$$

which is equivalent to (21) with M replaced by its average value along the path.

IV. OBSERVABLES

We have seen in the preceding section that the instanton picture of tunneling, with instantons corresponding to vortices and antivortices moving along closed paths in the Euclidean time, provides a very appealing and intuitive picture of flux tunneling across a wire of width $L_x \gg \xi$. This picture has allowed us to estimate the effects of the environment and to obtain the main exponential factor in the tunneling amplitude. However, for certain tasks, in particular for understanding the adiabatic limit, it is more convenient to use the dual description (9). In this section, we discuss what observables can be calculated in that dual theory that will contain information about tunneling.

We will be interested primarily in two observables. The first is the average vortex current. The corresponding operator is given by (7); in our present case, only J_x has a nontrivial average. To reduce the number of factors of $\hbar$ in the subsequent formulas, it is convenient to introduce instead of χ a new field

$$X = \frac{\chi}{\sqrt{\hbar}} \ . \tag{25}$$

Then,

$$J_x = -ic_1^2 \left[X^\dagger \partial_x X - \partial_x X^\dagger X - \frac{id}{2e} E(t) X^\dagger X \right] \ . \tag{26}$$

For our cylindrical configuration, the field X satisfies periodic boundary conditions in the x direction. The boundary conditions in the y direction will not matter; we take them to be periodic as well. The Fourier expansion of X is

$$X(\mathbf{x}, t) = \sum_{\mathbf{k}} \left(\alpha_{\mathbf{k}} f_{\mathbf{k}}(t) + \beta^\dagger_{-\mathbf{k}} f^*_{\mathbf{k}} \right) e^{i\mathbf{k}\mathbf{x}} \ , \tag{27}$$

where $\mathbf{k} = (k_x, k_y)$, α and β are the usual annihilation operators, and the mode functions satisfy

$$\ddot{f}_{\mathbf{k}} + \omega^2_{\mathbf{k}}(t) f_{\mathbf{k}} = 0 \tag{28}$$

with a time-dependent frequency

$$\omega^2_{\mathbf{k}}(t) = c_1^2 k_y^2 + c_1^2 \left[k_x - \frac{d}{4e} E(t) \right]^2 + M^2(t) \ . \tag{29}$$

To achieve the correct commutation relation between X and $\partial_t X$, the mode functions f should be normalized by the condition

$$f_{\mathbf{k}} \dot{f}^*_{\mathbf{k}} - \dot{f}_{\mathbf{k}} f^*_{\mathbf{k}} = \frac{i}{V} \ , \tag{30}$$

where V is the total two-dimensional volume. At some initial time $t = t_i$, before the pulse, we have $E(t_i) = 0$ and $M(t_i) = M_0$, so we can use the usual plane-wave exponentials as initial conditions for $f_{\mathbf{k}}(t)$. Equivalently,

$$f_{\mathbf{k}}(t_i) = [2\omega_{\mathbf{k}}(t_i) V]^{-1/2} \ , \tag{31}$$

$$\dot{f}_{\mathbf{k}}(t_i) = -i\omega_k f_{\mathbf{k}}(t_i) \ , \tag{32}$$

where $\omega^2_{\mathbf{k}}(t_i) = c_1^2 k^2 + M_0^2$.

As discussed in the preceding sections, to include the effect of the vortex-antivortex potential, the frequency $M(t)$ in these formulas is taken to be the average frequency along the vortex path. We note also that eq. (28) with the initial conditions (31)–(32) can be used for numerical studies of vortex transport [24].

Substituting (27) in (26), and assuming that the quantum state of the system is the vacuum of the operators α and β, we obtain the average current as

$$\langle J_x(t) \rangle = 2c_1^2 \sum_{\mathbf{k}} \left[k_x - \frac{d}{4e} E(t) \right] |f_{\mathbf{k}}|^2 \ . \tag{33}$$

The integral of this over time gives the average total vortex number transported around the cylinder (i.e. in the x

direction), per unit length in the y direction. So, it measures the efficiency of the amplitude transfer between the basis states of the qubit.

The second quantity of interest is a measure of the residual excitation left in the system after the pulse. It is simply the total average number of vortices left at some final time $t = t_f$ and is obtained as the sum $\sum_{\mathbf{k}} n_{\mathbf{k}}(t_f)$ of the occupation numbers of all the individual modes. These occupation numbers, as functions of time, are given by

$$n_{\mathbf{k}}(t) = \frac{V}{2\omega_{\mathbf{k}}(t)} \left[|\dot{f}_{\mathbf{k}}(t)|^2 + \omega_{\mathbf{k}}^2(t) |f_{\mathbf{k}}(t)|^2 \right] - \frac{1}{2} \,. \quad (34)$$

Our next goal will be to show that a sufficiently slow, adiabatic change in E and M can lead to a sizable transport of the vortex number, while leaving $n_{\mathbf{k}}(t \to \infty)$ exponentially suppressed.

V. ADIABATIC LIMIT

When the frequency (29) for each mode changes with time slowly (adiabatically), i.e.

$$|\partial_t \omega_{\mathbf{k}}| \ll \omega_{\mathbf{k}}^2 \,, \quad (35)$$

the adiabatic theorem [29] guarantees that particle production will be absent in any finite order in $|\partial_t \omega_{\mathbf{k}}|/\omega_{\mathbf{k}}^2$. In other words, $n_{\mathbf{k}}(t)$, which was zero initially, will be zero at $t \to \infty$ to exponential accuracy. The mode functions can then be approximated by WKB-type expressions:

$$f_{\mathbf{k}}(t) \approx [2\omega_{\mathbf{k}}(t) V]^{-1/2} \exp\left\{ -i \int_{t_i}^{t} \omega_{\mathbf{k}}(t') dt' \right\} \,. \quad (36)$$

Substituting this into (33), we obtain the average current as

$$\langle J_x(t) \rangle \approx \frac{c_1^2}{V} \sum_{\mathbf{k}} \frac{1}{\omega_{\mathbf{k}}(t)} \left[k_x - \tilde{E}(t) \right] \,, \quad (37)$$

where we have introduced notation

$$\tilde{E}(t) \equiv \frac{d}{4e} E(t) \,. \quad (38)$$

The summand in (37) depends on k_x only in combination $k_x - \tilde{E}$, and it is odd in that combination. So, if we could replace the sum over k_x by an integral and make a shift of the integration variable, we would prove that (37) is zero. There are, however, two obstructions to this procedure. First, the integral needs an ultraviolet regularization, which we take to be symmetric in k_x, not in $k_x - \tilde{E}$. As a result, the far ultraviolet modes contribute a finite amount proportional to $\tilde{E}$. Second, the difference between the sum and the integral results in a correction, which is periodic in $\tilde{E}$ with period $2\pi/L_x$, where L_x is the circumference of the cylinder. This correction vanishes when $\tilde{E}$ is an integer multiple of π/L_x, but is finite otherwise. It will be important for us to understand the structure of this correction.

To make the argument more transparent, let us consider the case of a weak electric field, $|\tilde{E}| \ll 2\pi/L_x$, so that we can expand the expected periodic correction in $\tilde{E}$. To simplify things even further, we will also assume that

$$b' = \frac{M L_x}{2c_1} \gg 1 \,. \quad (39)$$

Then, we can expand $1/\omega_{\mathbf{k}}$ in (37) in $\tilde{E}$, to obtain

$$\frac{1}{\omega_{\mathbf{k}}}(k_x - \tilde{E}) = (k^2 + M^2)^{-1/2} \left\{ k_x - \frac{c_1^2 k_y^2 + M^2}{c_1^2 k^2 + M^2} \tilde{E} + O(\tilde{E}^2) \right\} \,. \quad (40)$$

The first term in the braces gives zero upon summation over k_x (assuming a symmetric ultraviolet cutoff), so we have

$$\langle J_x(t) \rangle \approx -\frac{c_1^2 \tilde{E}}{V} \sum_{k_y} m^2 \sum_{k_x} \frac{1}{(c_1^2 k_x^2 + m^2)^{3/2}} + O(\tilde{E}^2) \,, \quad (41)$$

where

$$m^2 = c_1^2 k_y^2 + M^2 \,. \quad (42)$$

To compute the sum over k_x in (41), we use the representation

$$\sum_{n=-\infty}^{\infty} \frac{1}{(\pi^2 n^2 + b^2)^{3/2}} = \frac{2}{\pi b^2} \left(1 + \int_b^\infty \frac{\omega d\omega}{\sqrt{\omega^2 - b^2}\, \sinh^2 \omega} \right) \,; \quad (43)$$

in our case

$$b = \frac{m L_x}{2c_1} \,. \quad (44)$$

Under the condition (39), b is large, and we can expand the integral in (43) in e^{-2b}. We obtain

$$\sum_{k_x} \frac{1}{(c_1^2 k_x^2 + m^2)^{3/2}} = \frac{L_x}{\pi c_1 m^2} \left[1 + 2\sqrt{\pi b} e^{-2b} + O(e^{-4b}) \right] \,. \quad (45)$$

If we were to neglect the discreteness of modes, i.e. replace the sum on the left-hand side of (45) with an integral, we would obtain only the first term in the bracket. According to (41), the average current due to this term is proportional to E, with no other time-dependent factors (the factors of m^2 cancel out). In the absence of sources

of dissipation, such as pair-produced quasiparticles or real (non-virtual) vortices, we have $E = -(1/c)\partial_t A$, so the integral of E over time is zero. Thus, the total vortex number transported around the cylinder is determined entirely by the exponential correction in (45).

The remaining sum over k_y can be replaced by an integral and easily evaluated, noting that, at large values of b', e^{-2b} confines k_y to rather small values: $c_1^2 k_y^2 \sim M^2/b'$. Thus, in the limit (39) we finally obtain

$$\int dt \langle J_x(t) \rangle \approx -\frac{1}{\pi} \int dt \tilde{E} M \exp(-M L_x/c_1) \ . \qquad (46)$$

This quantity has dimension of inverse length, as it gives the transported vortex number per unit length of the cylinder.

The exponential factor in (46) coincides with the one obtained in sect. III by means of instanton calculus. Moreover, the periodicity with respect to $\tilde{E}$, noted after eq. (38), has a simple explanation in the instanton picture. Indeed, from (11) we see that the product $\tilde{E} L_x$ equals (up to a constant) the "solenoidal flux" $\int a_x dx$. So, for $\tilde{E} \neq 0$ the amplitudes due to a single instanton and a single antiinstanton acquire opposite phases, equal in magnitude to $|\tilde{E} L_x|$. In the limit (39), when the instanton gas is dilute, the average vortex current is then proportional to

$$\exp(-M L_x/c_1) \sin \tilde{E} L_x \ , \qquad (47)$$

which has precisely the same periodicity as that deduced from eq. (37). We stress that in the dual calculation these results appear as a consequence of the quantization of vortex modes in a confined geometry, without any reference to instantons. So, the present calculation is complementary to the instanton calculation of sect. III.

Note that eq. (46) determines also the value of the preexponent. As we have already discussed, unlike the exponent, the preexponent may in certain cases be affected by fermions at the vortex core. Any such modification will be absent from eq. (46). We will, however, continue to use this equation, since our main conclusions are based on the value of the exponential factor.

The exponential suppression seen in (46) is of entirely different origin—and, hence, generally of different magnitude—than the adiabatic suppression of $n_{\mathbf{k}}$. To remove the exponential suppression in (46) altogether, we need, at some time t during the pulse, to go just outside the limit (39), i.e. achieve the condition

$$M(t) = c_1/L_x \ . \qquad (48)$$

(At this point, the $O(e^{-4b})$ terms in (45) will become important.) Eq. (48) will not jeopardize adiabaticity provided that the characteristic timescale t_p of the pulse (e.g. the ramp time) satisfies

$$t_p/2\pi \gg 1/M(t) = L_x/c_1 \ . \qquad (49)$$

On the other hand, one can choose parameters of the device so that, before and after the pulse, the probability of random "errors", i.e., spontaneous transitions between the basis states, is vanishingly small. (The amplitude of such spontaneous transitions is proportional to $\exp(-M_0 L_x/c_1)$, where M_0 is the unperturbed initial mass.)

VI. NUMERICAL ESTIMATES

Let us summarize various conditions we have obtained so far on the parameters of the system. One is the inequality (49), which is the condition that a significant (order 1) vortex number transport is compatible with the adiabatic suppression of production of real vortex pairs. Another is the condition of exponential suppression of spontaneous tunneling transitions ("errors"):

$$L_x \gg \lambda \equiv c_1/M_0 \ . \qquad (50)$$

The quantity λ here, of the dimension of length, is analogous to the Compton wavelength of an elementary particle.

To (49) and (50), we should add the condition that pair production of quasiparticles is also exponentially suppressed (since quasiparticles, like vortices, lead to decoherence[‡]) and the condition that the coherence length of the superconductor remains smaller than L_x, so that vortices remain well defined. These two conditions should be written so as to take into account the reduction of the superconducting gap $\bar{\Delta}$, and the corresponding increase in the coherence length $\bar{\xi}$, during the pulse:

$$t_p/2\pi \gg \hbar/\bar{\Delta}(t) = \frac{\hbar \bar{\xi}(t)}{\xi \Delta} \ , \qquad (51)$$

$$L_x \gg \bar{\xi}(t) \ . \qquad (52)$$

Quantities without the bar denote the unperturbed values, i.e. those before and after the pulse. We now obtain estimates for M_0, c_1, and λ.

To obtain these estimates we use the Ginzburg-Landau (GL) energy of superconductor

$$H_{\rm GL} = d \int d^2x \left[\zeta |(\nabla + ig\mathbf{A})\psi|^2 - |r||\psi|^2 + \frac{s}{2}|\psi|^4 \right] \ , \qquad (53)$$

where ζ, r, and s are parameters. Although this expression is strictly applicable only near critical temperature, we will use it at temperatures close to absolute

[‡]A quasiparticle pair can detect passage of flux through Aharonov-Bohm scattering. Although it remains to calculate how strong this effect actually is, we nevertheless impose the condition of negligible pair production below.

zero, where our device is supposed to operate, since all we need are order-of-magnitude estimates.

From the GL energy (53), M_0, which was defined as half of the threshold frequency required to produce a real vortex-antivortex pair, can be estimated as

$$\hbar M_0 \sim 2\pi d\zeta |\psi_0|^2 \ . \tag{54}$$

Here ψ_0 is the order parameter in the absence of current. This is an estimate for the "core" frequency. The long-range interaction between a vortex and an antivortex will contribute an additional amount, enhanced relative to (54) by $\ln L_x/\bar{\xi}$. However, since for the values of the parameters that we use below this logarithm is of order one, the estimate (54) will be sufficient for our purposes. It can be rewritten using the London screening length δ:

$$\hbar M_0 \sim \frac{e^2 d}{16\alpha_{\rm EM}^2 \delta^2} \ , \tag{55}$$

where $\delta^{-2} = 32\pi e^2 \zeta |\psi_0|^2/\hbar^2 c^2$, and $\alpha_{\rm EM}$ is the fine structure constant. (In thin films, δ determines the strength of the London current but not the actual screening length of the vortex magnetic field.)

We now turn to estimating the limiting speed c_1, or equivalently the vortex inertial mass (12). There are two types of contributions to m [27,17]: from the electric field caused by the vortex motion and from core fermions. We have discussed the mass due to core fermions in sect. III and have seen that for vortex tunneling, characterized by short timescales, the effect is not as large as for slow motions: on a short timescale the vortex cannot transfer a large longitudinal momentum to the fermion subsystem. In particular, the core contribution to the mass does not affect the value of the instanton exponent. Accordingly, for our estimates we take m to be given by the small electromagnetic mass of the vortex

$$m \sim \frac{\hbar^2 d}{16 e^2 \xi^2} \ . \tag{56}$$

(See refs. [16,17,10] for how this estimate can be obtained.) This estimate results in a large value of c_1:

$$c_1 \sim (\xi/\delta) c \ . \tag{57}$$

The vortex's "Compton wavelength" can be now obtained from (50):

$$\lambda \sim \frac{16\alpha_{\rm EM}\xi\delta}{d} \ . \tag{58}$$

For numerical estimates, we use the following values: $d = 10$ nm, $\xi = 30$ nm, and $\delta = 100$ nm. Then, according to (58), $\lambda \sim 35$ nm, and (50) suggests that to suppress spontaneous transitions it is sufficient to use L_x of order 1 μm. Comparing (48) and (50), we see that in this case the pulse will need to reduce the vortex frequency M by a factor

$$\frac{M_0}{M(t)} = \frac{L_x}{\lambda} \sim 30 \ . \tag{59}$$

Because $M(t)$ depends quadratically on the gap $\bar{\Delta}(t)$ (cf. (54)), eq. (59) corresponds to a reduction in $\bar{\Delta}$, and an increase in $\bar{\xi}$, by a factor of order 5. For a superconductor with a quasiparticle gap $\Delta = 10$ K, this turns the condition (51) into

$$t_p/2\pi \gg 4 \times 10^{-12} \text{ s} \ . \tag{60}$$

Meanwhile, the competing condition (49) is

$$t_p/2\pi \gg 10^{-14} \text{ s} \ . \tag{61}$$

So, for the above values of the parameters, adiabaticity with respect to quasiparticle production is a stronger condition than adiabaticity with respect to production of vortices. Finally, the condition (52) can be easily verified.

VII. CONCLUSION

Our main result is the demonstration that for topological transitions, involving transport of magnetic flux via vortices, there exists a potentially useful adiabatic limit. In that limit, the probability to produce real vortex or quasiparticle pairs is exponentially small (as might be expected), but the transport of the vortex number due to *virtual* vortices can in principle be of order one.

Our choice of the cylindrical geometry was motivated by the ease of imposing boundary conditions on the vortex field in the dual formulation. We expect the result to apply to other geometries, which may also be easier to fabricate.

We have presented two calculations of the leading exponential factor in the tunneling amplitude: one based on instantons, and the other based on the dual formulation, in which vortices are described by a fundamental quantum field. The results have been shown to agree.

In addition, the instanton approach has allowed us to estimate the effects of the core fermions on vortex tunneling. The process at hand, i.e. an adiabatic transition in which no vortices are produced in the final state, turns out to have a very short (Euclidean) timescale, resulting in only a small transfer of longitudinal momentum to the fermions. As a consequence, the effective inertial mass of the vortex during tunneling is much smaller than the known estimates corresponding to slow motions. We have also discussed the effect of the vortex-antivortex potential and have found that, for calculating the leading exponential factor, the position-dependent vortex mass can be replaced with its average over the vortex path.

Our calculations were done under the condition that the wire width L_x (the circumference of the cylinder) exceeds the GL coherence length ξ, so that vortices remain well defined. (This is the limit opposite to that of an ultra-thin wire, where tunneling is due to quantum phase slips.) Our results suggest that for L_x in the

micron range, induced vortex tunneling may be experimentally observable.

Moreover, since the adiabatic limit, i.e. a slow switching on and off of the current, eliminate the most obvious sources of decoherence, namely, pair production of vortices or quasiparticles, the process may be suitable for forming quantum superpositions of flux states. There are other possible sources of decoherence, in particular those due to components of the environment, such as nuclear or impurity spins, that are sensitive to magnetic fields caused by persistent currents, but we do not expect the situation here to be worse than for the conventional SQUID designs [30].
